Abstract
In automata theory, the quantum computation has been widely examined for finite state machines, known as quantum finite automata (QFAs), and less attention has been given to the QFAs augmented with counters or stacks. Moreover, to our knowledge, there is no result related to QFAs having more than one input head. In this paper, we focus on such generalizations of QFAs whose input head(s) operate(s) in one-way or realtime mode and present many superiority of them to their classical counterparts. Furthermore, we propose some open problems and conjectures in order to investigate the power of quantumness better. We also give some new results on classical computation.

keywords: *quantum computation, randomization, quantum automata, pushdown automaton, blind counter automaton, multihead finite automaton, nondeterminism, bounded error*

1. Introduction

Quantum computation is a generalization of classical computation [33, 42]. Therefore, it is interesting to investigate the cases in which quantum computation is superior to classical computation. In automata theory, many superiority results have been obtained mostly for quantum finite automata[1] (QFAs) [1, 3, 5, 6, 8, 17, 20, 21, 28, 29, 38–42] and a few for QFAs with counters [7, 18, 30, 36, 43, 44] and for QFAs with a stack [13, 20, 23, 24].

In this paper, we present many new results about how the quantumness and in some cases randomness adds power to the one-way and realtime computational models, i.e. multihead finite and pushdown automata, counter automata, etc. Then, we present some open problems and conjectures for the further investigations. We also give some new results about classical computation.

Due to their restricted definitions, early QFA models and their variants were shown to be less powerful than their classical counterparts for many cases [1,2,17,22,43]. In fact, these models do

---

*This work was partially supported by TÜBİTAK with grant 108E142 and FP7 FET-Open project QCS.

[1] They are also known as quantum Turing machines with constant space.

not reflect the full power of quantum computation [34]. Therefore, we use "modern" definitions for the quantum models (e.g. [4,15]).

After a concise background given in Section 2, we present our results in Section 3, in which we classify the results under four subsections: (3.1) nondeterminism, (3.2) blind counter automata, (3.3) multihead finite automata, and (3.4) multihead pushdown automata.

2. Background

We specifically give the definitions of three models in order to trace the proofs presented in the paper: generalized finite automaton, one-way quantum finite automaton, and realtime quantum automaton with one-blind counter. The quantum models are defined based on a generic template that is given in Subsection (3.2). We refer the reader to [10,14,16,27,31] for the definitions of classical machines; to [15,42] for the definitions of the QFAs generalizing their classical counterparts; and, to [25] for a standard reference of quantum computation.

Throughout the paper, we use the following notations: Σ not containing ¢ and \$ (the left and right end-markers) denotes the input alphabet; $\tilde{\Sigma} = \Sigma \cup \{¢, \$\}$; Q is the set of (internal) states; $q_0 \in Q$ is the initial state; $Q_a \subseteq Q$ is the set of accepting states; δ is the transition function; $f_{\mathcal{M}}(w)$ is the accepting probability (or value) of machine $\mathcal{M}$ on w; w_i is the i^{th} symbol of w; $|w|$ is the length of w; $|w|_\sigma$ is the number of the occurrence of σ in w, where $w \in \Sigma^*$. The list of abbreviations used for models is given below:

- the prefixes "1" and "rt" stand for *one-way*[2] and *realtime*[3] input head(s), respectively;
- the letters "D", "N", "P", and "Q" used after "1" or "rt" stand for *deterministic*, *nondeterministic*, *probabilistic*, and *quantum*, respectively;
- the abbreviations "FA", "kFA", "PDA", "PDkA", and "kBCA" stand for *finite automaton*, *finite automaton with k input heads*, *pushdown automaton*, *pushdown automaton with k input heads*, and *automaton with k blind counter(s)*, respectively, where $k > 0$.

For all models (except GFAs), the input $w \in \Sigma^*$ is placed on a read-only two-way infinite tape as $\tilde{w} = ¢w\$$ from the squares indexed by 1 to $|\tilde{w}|$. At the beginning, the head(s) is (are) initially placed on the square indexed by 1 and the value(s) of the counter(s) is (are) set to zero.

2.1. Generalized finite automaton

A generalized finite automaton (GFA) [32] is formally a 5-tuple

$$\mathcal{G} = (Q, \Sigma, \{A_{\sigma\in\Sigma}\}, v_0, f),$$

---

[2] The input head(s) is (are) not allowed to move to left.

[3] The input head(s) is (are) allowed to move only to the right.

where (i) $A_{\sigma\in\Sigma}$'s are $|Q|\times|Q|$-dimensional real valued transition matrices, and, (ii) v_0 and f are real valued *initial* (column) and *final* (row) vectors, respectively. For an input string, $w\in\Sigma^*$, the acceptance value of w associated by $\mathcal{G}$ is defined as

$$f_{\mathcal{G}}(w) = fA_{w_{|w|}}\cdots A_{w_1}v_0.$$

2.2. Generic templete for quantum machines

Now, we briefly describe a general framework for quantum machines allowing to implement general quantum operators (see [35, 42] for details). Each quantum machine has a special component, a finite register, not considered as a part of the configurations, with alphabet Ω having a distinguished symbol ω_1 (the initial symbol). In each step of the transition, (i) the register is reset to $|\omega_1\rangle$; (ii) as a part of the transition, a symbol is written on the register; and, (iii) the finite register is discarded. For one-way models, we have a set of outcomes $\Delta = \{a, r, n\}$ (Ω is partitioned into there pairwise disjoint subsets, i.e. $\Omega_{\tau\in\Delta}$) and, before discarding process, a projective measurement is applied on the register. That is, $P = \{P_{\tau\in\Delta} \mid P_\tau = \sum_{\omega\in\Omega_\tau}|\omega\rangle\langle\omega|\}$, and the following actions are performed with respect to the outcomes: (a) or (r) the computation is halted and the input is accepted or rejected, respectively, (n) the computation continues. For realtime models, the decision on the input is given after reading the whole input by a projective measurement, applied on the space spanned by the internal states, i.e. $P = \{P_a, I - P_a \mid P_a = \sum_{q\in Q_a}|q\rangle\langle q|\}$. For the models with blind counters, an additional measurement is done on the counters to check whether their values are zero or not.

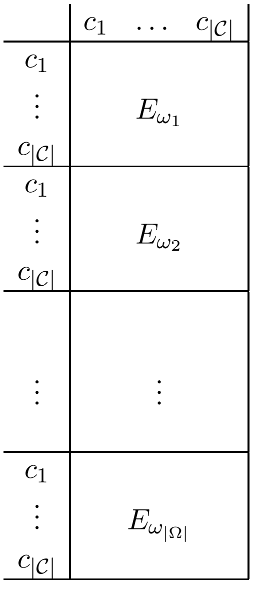

Figure 1: Matrix E

A quantum machine operates on the space spanned by its configurations. The computation begins with the initial configuration and continues until terminated. The transitions between the configurations are determined by the transition function. Let $\mathcal{C}^w_{\mathcal{M}}$, shortly $\mathcal{C}$, be the configuration set of $\mathcal{M}$ for a given input $w\in\Sigma^*$. All transitions of $\mathcal{M}$ on w can be summarized as in Figure 1, in which $E_{\omega \in \Omega}$ represents all transitions between the configurations when ω is written on the register. To be a well-formed machine, for all $w \in \Sigma^*$, the columns of the matrix E (Figure 1) form an orthonormal set[4], i.e. equivalently,

$$\sum_{\omega \in \Omega} E_\omega^\dagger E_\omega = I,$$

where $E_\omega[j,i]$ denotes the amplitude of transition from the i^{th} configuration to j^{th} configuration by writing ω on the register.

2.3. One-way quantum finite automata

A one-way quantum finite automata (1QFA) [42] is a 7-tuple

$$\mathcal{M} = (Q, \Sigma, \Omega, \delta, q_0, \Omega_a, \Omega_r),$$

where Ω_a (Ω_r) is the set of accepting (rejecting) symbols. The transition of $\mathcal{M}$ is specified as:

$$\delta(q, \sigma) = \alpha(p, d, \omega) \quad (\alpha \in \mathbb{C}), \tag{1}$$

where $\mathcal{M}$, which is in state $q \in Q$ and reads $\sigma \in \Sigma$ on the input tape, changes the internal state to $p \in Q$, update the position of the input head with respect to $d \in \{\downarrow, \rightarrow\}$, and writes $\omega \in \Omega$ on the finite register with amplitude α. For simplicity, we assume that range component d can be determined by component p, denoted $\downarrow p$ and $\overrightarrow{p}$, and so term d can be dropped from Equation 1. For a given string $w \in \Sigma^*$, the configurations of $\mathcal{M}$ are the pairs of $(q, x) \in Q \times \{1, \ldots, |\tilde{w}|\}$ and $(q_1, 1)$ is the initial one, where x stands for the head position.

2.4. Realtime quantum automaton with 1 blind counter

A realtime quantum automata with one blind counter (rtQ1BCA) is a 6-tuple

$$\mathcal{M} = (Q, \Sigma, \Omega, \delta, q_0, Q_a).$$

We assume that $\mathcal{M}$ can have the capability[5] of updating its counter(s) from the set $\{-m, \ldots, m\}$ for any fixed $m > 1$. The transition of $\mathcal{M}$ is specified as:

$$\delta(q, \sigma) = \alpha(p, c, \omega) \quad (\alpha \in \mathbb{C}), \tag{2}$$

where $\mathcal{M}$, which is in state $q \in Q$ and reads $\sigma \in \Sigma$ on the input tape, changes the internal state to $p \in Q$, update the counter value by $c \in \{-m, \ldots, m\}$, and writes $\omega \in \Omega$ on the finite register with amplitude α. For a given string $w \in \Sigma^*$, the configurations of $\mathcal{M}$ are the pairs of $(q, v) \in Q \times \mathbb{Z}$ and $(q_1, 0)$ is the initial one, where v stands for the value of the counter.

---

[4] In fact, matrix E (Figure 1) is a part of a bigger unitary matrix, say U, that is responsible for the evolution of configuration space joint with the finite register. Since the register is reset to $|\omega_1\rangle$ in each step, only a part of U, which is exactly E, operates on the configuration space. Therefore, the columns of E must be orthonormal.

[5] It is a well-known fact that (e.g. see [36]) for any classical or quantum counter automata having the capability of updating its counter(s) from the set $\{-m, \ldots, m\}$, there exists an equivalent counter automaton updating its counter(s) from the set $\{-1, 0, 1\}$ for any $m > 1$.

2.5. Language recognition

The language recognition criteria used in the paper can be defined as follows:

- A language $L \subseteq \Sigma^*$ is said to be recognized by $\mathcal{M}$ with error bound $\epsilon \in (0, \frac{1}{2})$ if (i) $f_{\mathcal{M}}(w) \geq 1 - \epsilon$ for $w \in L$ and (ii) $f_{\mathcal{M}}(w) \leq \epsilon$ for $w \notin L$.
- A language $L \subseteq \Sigma^*$ is said to be recognized by $\mathcal{M}$ with negative one-sided error bound $\epsilon \in (0, 1)$ if (i) $f_{\mathcal{M}}(w) = 1$ for $w \in L$ and (ii) $f_{\mathcal{M}}(w) \leq \epsilon$ for $w \notin L$.
- A language $L \subseteq \Sigma^*$ is said to be recognized by $\mathcal{M}$ in nondeterministic mode if (i) $f_{\mathcal{M}}(w) > 0$ for $w \in L$ and (ii) $f_{\mathcal{M}}(w) = 0$ for $w \notin L$.

Note that, any negative one-sided error bound $\frac{1}{2}$ can be easily converted to the general error bound $\frac{1}{3}$ and any negative one-sided error bound in internal $(\frac{1}{2}, 1)$ can be easily converted to a general error bound in interval $(\frac{1}{3}, \frac{1}{2})$. Moreover, as a special case, the class of languages recognized by rtQFAs in nondeterministic mode is denoted by NQAL [39].

3. Main results

In our algorithms, we use a special kind of quantum transformation, N**-way QFT** (quantum Fourier transform) [17, 36, 37]. Let $N > 1$ be a integer. The N-way QFT is the transformation

$$\delta(d_j) = \frac{1}{\sqrt{N}} \sum_{l=1}^{N} e^{\frac{2\pi i}{N} jl} (r_l), \qquad 1 \leq j \leq N,$$

from the *domain* elements $d_1, \ldots, d_N$ to the *range* (*target*) elements $r_1, \ldots, r_N$, where r_N is the distinguished target elements. The QFT can be used to check whether separate computational paths of a quantum program that are in superposition have converged to the same configuration at a particular step. Assume that the program has previously split to N paths, say s_j ($1 \leq j \leq N$), each of which have the same amplitude. We assume that s_j (when having d_j) enters to $s_{j,1}, \ldots, s_{j,N}$ by the QFT. If $s_{j,l} \neq s_{j',l}$ for each $j \neq j'$, then none of the target elements is interfered with each other and so the distinguished target exists with probability $\frac{1}{N}$, where $1 \leq l \leq N$. Otherwise, if each s_j makes the QFT in different computational steps, then we obtain the same result. But, if all of them make the QFT simultaneously, then all targets are interfered with each other and only the distinguished target survives with probability 1.

3.1. Nondeterminism

It was shown in [39] that $L \subseteq \Sigma^* \in$ NQAL if and only if L is defined by a GFA, say $\mathcal{G}$, as follows: (i) $f_{\mathcal{G}}(w) > 0$ for $w \in L$ and (ii) $f_{\mathcal{G}}(w) = 0$ for $w \notin L$. We show our results in this section based on this equivalence.

We already know that the class of languages recognized by 1NFAs (reps., 1NPDAs) is a proper subset of the class of languages recognized by rtQFAs (resp., 1QPDA) in nondeterministic mode [24, 39]. We give a stronger version of these results by using noncontextfree language $L_{ijk} = \{a^i b^j c^k \mid i \neq j, i \neq k, j \neq k, 0 \leq i, j, k\}$.

Theorem 1. *L_{ijk} is in NQAL.*

Proof. (See Appendix A for a complete proof) We can design a GFA to calculate the value of $(|w|_a - |w|_b)$ on a specified internal state. By tensoring this machine with itself, we can obtain the value of $(|w|_a - |w|_b)^2$. Similarly, we can also calculate the value of

$$(|w|_a - |w|_b)^2(|w|_a - |w|_c)^2(|w|_b - |w|_c)^2.$$

Additionally, this value is multiplied by 0 if the input is not of the form $a^+b^+c^+$. Therefore, the last result is a positive integer if $w \in L_{ijk}$ and it is zero if $w \notin L_{ijk}$. □

Corollary 1. *In nondeterministic mode, the class of the languages recognized by classical machines is a proper subset of the class of the languages recognized by quantum machines for any model between finite automaton and one-head pushdown automaton.*

Now we give a separation result between deterministic and nondeterministic automata with blind counters. Note that, every one-way versions of these models can be easily converted to ones operating in realtime.

Theorem 2. *If L is recognized by a rtDkBCA, then $\overline{L}$ ∈NQAL, where $k > 0$.*

Proof. (See Appendix B for a complete proof) Let $\mathcal{D}$ be the rtDkBCA recognizing L. We can design a GFA, say $\mathcal{G}$, to exactly mimic the state transitions of $\mathcal{D}$. ($\mathcal{G}$ can also cover the transitions of $\mathcal{D}$ on ¢ and \$, by its initial and final vector component.) During the simulation, $\mathcal{G}$ additionally change the values of the internal states with respect to the following strategy: (let p_i be the i^{th} prime $(1 \leq i \leq k)$) (i) at the beginning, the value of the internal state of $\mathcal{G}$ corresponding to the initial state of $\mathcal{D}$ is 1, and, (ii) if the value of the i^{th} counter is updated by 1 (resp., -1), then the value of the state is multiplied by p_i (resp., $\frac{1}{p_i}$).

Suppose that, the computation of $\mathcal{D}$ ends in state q on input w. Let q' be the internal state of $\mathcal{G}$ corresponding to q and $c_{q'}$ be the value of q'. It can be easily be verified that $c_{q'} = 1$ if and only if all counters of $\mathcal{D}$ are set to zeros at the end of the computation. The value of $(c_{q'} - 1)^2$ can also be calculated by a GFA $\mathcal{G}'$ if q is an accepting state. So, for $w \in L$ ($w \notin L$), we have $f_{\mathcal{G}'}(w) = 0$ ($f_{\mathcal{G}'}(w) > 0$). □

In [12], it is shown that L_{say} cannot be recognized by a rtQFA with unbounded error (and so $L_{say} \notin$ NQAL and $\overline{L_{say}} \notin$ NQAL [42]), where

$$L_{say} = \{w \mid \exists u_1, u_2, v_1, v_2 \in \{a, b\}^*, w = u_1 b u_2 = v_1 b v_2, |u_1| = |v_2|\}.$$

However, it can be easily be shown that L_{say} can be recognized by a rtN1BCA: two b's (those can also be the same) can be selected nondeterministically and by using a blind counter, the lengths of the substrings before the first b and after the second b can be compared.

Corollary 2. *For any $k \in \mathbb{Z}^+$, the class of languages recognized by 1DkBCAs is a proper subset of the class of languages recognized by 1NkBCAs.*

3.2. Blind counter automata

Lemma 1. *For any $\epsilon \in (0, \frac{1}{2})$, $L_{upal} = \{a^n b^n \mid n \geq 0\}$ can be recognized by a rtQ1BCA with negative one-sided error bound ϵ.*

Proof. Let $N \geq 2$ and $\mathcal{M}_{upal,N} = (Q, \Sigma, \Omega, \delta, q_0, Q_a)$ be a rtQ1BCA, where $Q = \{q_0, a_0, r_0\} \cup \{q_j \cup q'_j \cup p_j \cup r_j \mid 1 \leq j \leq N\}$, $\Omega = \{\omega_1, \omega_2, \omega_r\}$, $Q_a = \{a_0, p_N\}$. The details of δ is given in Figure 2. (The missing part of δ can be easily be completed.)

We show that $\mathcal{M}_{upal,N}$ recognizes L_{upal} with negative one-sided error bound $\frac{1}{N}$. Therefore, by setting $N = \lceil \frac{1}{\epsilon} \rceil$, we obtain the desired machine.

Figure 2: The details of the transition function of $\mathcal{M}_{upal,N}$

We begin with two trivial cases: (i) if the input is empty string, then it is accepted with probability 1; (ii) if the input begins with a b, then it is rejected with probability 1. So, we assume the input to begin with an a in the remaining part. After reading the first a, the computation is split into N different paths, path_j $(1 \leq j \leq N)$, with amplitude $\frac{1}{\sqrt{N}}$ and the counter value is increased by j in path_j. Each path keeps the same increment strategy as long as reading a's. After reading a b, each path switches to a decrement strategy such that the counter value is decreased by j in path_j as long as reading b's.

If an a is read after a b, $\mathsf{path_j}$ passes to $\mathsf{rejecting\text{-}path_j}$, in which the input is rejected with probability 1 at the end. Otherwise, the input is of the form $a^m b^n$, where $m > 0$ and $n \geq 0$, and before reading \$, the machine is in the following superposition (of the configurations):

$$\sum_{j=1}^{N} \frac{1}{\sqrt{N}} |(q'_j, j(m-n))\rangle.$$

Note that, if $m = n$, then we have

$$\sum_{j=1}^{N} \frac{1}{\sqrt{N}} |(q'_j, 0)\rangle.$$

Thus, after reading \$, each path enters an N-way QFT. That is, (i) if $m = n$, all configurations are interfered with each other and only $|(p_N, 0)\rangle$ remains with probability 1 and so the input is accepted exactly; (ii) if $m \neq n$, none of the configuration is interfered and so the input is accepted with probability $\frac{1}{N}$ – before the measurement, the configurations with p_N exist in the superposition as

$$\sum_{j=1}^{N} \frac{1}{N} |(p_N, j(m-n))\rangle.$$

Note that, in case of $m \neq n$, the configurations with an internal state different than q_N are observed with probability $1 - \frac{1}{N}$ at the end. □

Theorem 3. *For any $\epsilon \in (0, \frac{1}{2})$, L^*_{upal} can be recognized by a rtQ1BCA with negative one-sided error bound ϵ.*

Proof. We use the idea presented in the proof of Lemma 1 after making a small modification. Let $N \geq 2$ and $\mathcal{M}_{upal^*,N} = (Q, \Sigma, \Omega, \delta, q_0, Q_a)$ be a rtQ1BCA, where $Q = \{q_0, a_0, r_0\} \cup \{q_j \cup q'_j \cup p_j \mid 1 \leq j \leq N\} \cup \{r_j \mid 1 \leq j \leq N-1\}$, $\Omega = \{\omega_1, \omega_2, \omega_3, \omega_r\}$, $Q_a = \{a_0, p_N\}$. The details of δ is given in Figure 3. (The missing part of δ can be easily be completed.)

Figure 3: The details of the transition function of $\mathcal{M}^*_{upal,N}$

Suppose that the input is of the form $(a^+b^+)(a^+b^+)^+$ or $(a^+b^+)(a^+b^+)^*a^+$. (If not, $\mathcal{M}_{upal^*,N}$ behaves exactly the same as $\mathcal{M}_{upal,N}$.) After reading the first block of (a^+b^+), $\mathcal{M}_{upal^*,N}$ enters a QFT on the first a to compare the number of a's and the number of b's in the block. The targets of the QFT are $\textsf{rejecting-path}_{\textsf{j}}$'s ($1 \leq j \leq N-1$) and the distinguished one in which the computation re-splits into $\textsf{path}_k$'s ($1 \leq k \leq N$) with equal amplitudes. Thus, if the block contains the equal number of a's and b's, only the distinguished target remains and the computation goes on in $\textsf{path}_k$'s with probability 1. Otherwise, with probability $1-\frac{1}{N}$, the computation enters $\textsf{rejecting-path}_{\textsf{j}}$'s, in which the input is rejected certainly at the end. The same procedure is repeated for each (a^+b^+) block that is followed by an a in $\textsf{path}_k$'s. When reading \$, the computation again enters a final QFT in $\textsf{path}_k$'s such that the distinguished target is a configuration with the accepting state p_N.

Therefore, the members of L^*_{upal} are accepted exactly and the nonmebers are rejected with probability at least $1-\frac{1}{N}$. By setting $N = \lceil \frac{1}{\epsilon} \rceil$, we obtain the desired machine. □

In [14], it was shown that L^*_{upal} cannot not recognized by any 1DkBCAs, where $k \in \mathbb{Z}^+$.

Corollary 3. *For any $k \in \mathbb{Z}^+$ and $\epsilon \in (0, \frac{1}{2})$, the class of languages recognized by 1DkBCAs is a proper subset of the class of the languages recognized by rtQkBCAs with error bound ϵ.*

Conjecture 1. *L^*_{upal} cannot be recognized by any 1PkBCA with bounded error, where $k > 0$.*

3.3. Multihead finite automata

Let $L_{upal(t)}$ and $L'_{upal(t)}$ be the following languages:

$$L_{upal(t)} = \{a^{n_1}b\cdots ba^{n_t}ba^{n_t}b\cdots ba^{n_1} \mid n_i \geq 0, 1 \leq i \leq t\}$$

and

$$L'_{upal(t)} = \{a^{n_1}b\cdots ba^{n_t}ba^{n_t}b\cdots ba^{n_1} \mid n_i > 0, 1 \leq i \leq t\},$$

respectively. It was shown in [19] that for any k, there exists a $t > 0$ such that language $L'_{upal(t)}$ cannot be recognized by any 1NkFA. We can argue the same argument also for $L_{upal(t)}$ since any 1NkFA recognizing $L_{upal(t)}$ can be converted to a 1NkFA recognizing $L'_{upal(t)}$ in a straightforward way. On the other hand, we show that, for any $\epsilon \in (0, \frac{1}{2})$, $L_{upal(t)}$ can be recognized by a 1QFA or a 1P3FA with negative one-sided error bound ϵ.

Lemma 2. *For any $\epsilon \in (0, \frac{1}{2})$, language $L_{upal(1)}$ can be recognized by a 1QFA with negative one-sided error bound ϵ.*

Proof. We use a similar technique described in the proof of Lemma 1. Let $N = \lceil \frac{1}{\epsilon} \rceil$ and $\mathcal{M}_{upal(1),N} = (Q, \Sigma, \Omega, \delta, q_0, \Omega_a, \Omega_r)$ be a 1QFA, where $Q = \{\downarrow q_k \mid 0 \leq k \leq N\} \cup \{\overrightarrow{q_{j,1}} \cup \overrightarrow{p_{j,1}} \mid 1 \leq j \leq N\} \cup \{\downarrow q_{j,k} \mid 2 \leq k \leq j+1, 1 \leq j \leq N\} \cup \{\downarrow p_{j,k} \mid 2 \leq k \leq N-j+2, 1 \leq j \leq N\}$, $\Omega = \{\omega_n, \omega_a, \omega_r\}$, $\Omega_a = \{\omega_a\}$, and $\Omega_r = \{\omega_r\}$. The details of δ is given in Figure 4. (The missing part of δ can be easily be completed.)

¢
$\delta(\overrightarrow{q_0}, ¢) = \frac{1}{\sqrt{N}}(\overrightarrow{q_{j,1}}, \omega_n)$

$\mathsf{path_j}$ $(1 \leq j \leq N)$

a (before reading a b)	a (after reading a b)
$\delta(\overrightarrow{q_{j,1}}, a) = (\downarrow q_{j,2}, \omega_n)$ $\delta(\downarrow q_{j,k}, a) = (\downarrow q_{j,k+1}, \omega_n) \ \ (2 \leq k < j+1)$ $\delta(\downarrow q_{j,j+1}, a) = (\overrightarrow{q_{j,1}}, \omega_n)$	$\delta(\overrightarrow{p_{j,1}}, a) = (\downarrow p_{j,2}, \omega_n)$ $\delta(\downarrow q_{j,k}, a) = (\downarrow p_{j,k+1}, a, \omega_n) \ \ (2 \leq k < N-j+2)$ $\delta(\downarrow p_{j,N-j+2}, a) = (\overrightarrow{p_{j,1}}, \omega_n)$
b	$\$$
$\delta(\overrightarrow{q_{j,1}}, b) = (\overrightarrow{p_{j,1}}, \omega_n)$ $\delta(\overrightarrow{p_{j,1}}, b) = (\overrightarrow{p_{j,1}}, \omega_r)$	$\delta(\overrightarrow{q_{j,1}}, \$) = (\downarrow q_{j,2}, \omega_r)$ $\delta(\overrightarrow{p_{j,1}}, \$) = \frac{1}{\sqrt{N}} \sum_{l=1}^{N-1} e^{\frac{2\pi i}{N} jl}(\downarrow q_l, \omega_r) + \frac{1}{\sqrt{N}} e^{2\pi i j}(\downarrow q_N, \omega_a)$

Figure 4: The details of the transition function of $\mathcal{M}_{upal(1),N}$

We show that $\mathcal{M}_{upal(1),N}$ recognizes $L_{upal(1)}$ with negative one-sided error bound $\frac{1}{N}$. Therefore, by setting $N = \lceil \frac{1}{\epsilon} \rceil$, we obtain the desired machine.

On symbol ¢, the computation is split into N different paths, say path_i $(1 \leq i \leq N)$, with amplitude $\frac{1}{\sqrt{N}}$. If the input does not contain exactly one b, it is rejected in each path. We assume the input of the form $a^m b a^n$ $(m, n \geq 0)$ in the remaining part. Before (resp., after) reading symbol b, path_j waits j (resp., $N - j + 1$) step(s) on each a, and so, path_j arrives on \$ after making $m(j) + n(N - j + 1)$ stationary movements. After reading \$, each path makes a QFT: the input is accepted in the distinguished target and it is rejected, otherwise.

It can be easily verified that for any $j_1 \neq j_2$, path_{j_1} and path_{j_2} arrive on \$ simultaneously if and only if $m = n$, where $1 \leq j_1, j_2 \leq N$. In other words, each path makes the N-way QFT at the same time if and only if $m = n$. That is, (i) if $m = n$ (*the succeed case*), all paths are interfered with each other and only configuration $|(q_N, |w| + 2)\rangle$ remains with probability 1 and so the input is accepted exactly; (ii) otherwise (*the failure case*), none of the paths is interfered with the others and so the input is accepted with probability at most $\frac{1}{N}$. $\square$

Theorem 4. *For any $\epsilon \in (0, \frac{1}{2})$, language $L_{upal(t)}$ can be recognized by a 1QFA with negative one-sided error bound ϵ, where $t > 0$.*

Proof. (Sketch) The proof can be obtained by generalizing the technique presented in the proof of Lemma 2. Suppose that the input is of the form

$$a^{m_1} b \cdots b a^{m_t} b a^{n_t} b \cdots b a^{n_1} \ (m_i, n_i \geq 0 \text{ and } 1 \leq i \leq t).$$

(Otherwise, the input is rejected exactly.) The algorithm has t stages. In the first stage, the equality of m_t and n_t are compared. If so, the computation goes to next stage with probability 1. Otherwise, the input is rejected with probability $1 - \frac{1}{N}$ and the computation goes to next stage with probability $\frac{1}{N}$. In the second stage, the equality of m_{t-1} and n_{t-1} are compared in the same manner. The computation continues in this way and in the last stage, the input is accepted instead of going to next stage. Therefore, for the members, the input is accepted with probability 1 and for the nonmembers the input is accepted with probability at most $\frac{1}{N}$. Some technical details are given below. Let $N = \lceil \frac{1}{\epsilon} \rceil$.

1. On symbol ¢, the computation is split into N paths with equal amplitudes, say path_{j_1} ($1 \leq j_1 \leq N$). After reading the first b, the computation is again split into N paths with equal amplitudes, i.e. path_{j_1} is split into N paths path_{j_1,j_2} ($1 \leq j_1, j_2 \leq N$). This process is repeated until reading the $(t-1)^{th}$ b. Thus, after reading the $(t-1)^{th}$ b, each path has t indexes, i.e. $\mathsf{path}_{j_1,\ldots,j_t}$ ($1 \leq j_k \leq N$ and $1 \leq k \leq t$). Note that, any path with index $(j_1, j_2, \ldots, j_{k'})$ ($1 \leq k' \leq t$) is responsible to compare numbers $m_{k'}$ and $n_{k'}$.

2. Before (resp., after) reading the t^{th} b, if j is the last one in the index (of the path), then, it waits j (resp., $N - j + 1$) steps over each a.

3. After reading the t^{th} b, all paths start to make N-way QFT over each b in order to compare the numbers under their responsibility. After the QFT, the computation continues with the paths, from which the current paths were created in the previous steps (i.e. technically the rightmost one is dropped from the index) with probability 1 in the succeed case and with probability $\frac{1}{N}$ in the failure case. Note that, in the failure case, the computation is terminated and the input is rejected with probability $1 - \frac{1}{N}$. □

Corollary 4. *For any $k \in \mathbb{Z}^+$ and $\epsilon \in (0, \frac{1}{2})$, the class of languages recognized by 1DkFAs is a proper subset of the class of the languages recognized by 1QkFAs with error bound ϵ.*

In [11], Freivalds showed that, for any $\epsilon \in (0, \frac{1}{2})$, $L_{eq(t)}$ can be recognized by a rtP1BCA with negative one-sided error bound ϵ, where $t > 0$ and

$$L_{eq(t)} = \{w \in \{a_1, \ldots, a_t, b_1, \ldots, b_t\}^* \mid \forall i \in \{1, \ldots, t\}(|w|_{a_i} = |w|_{b_i})\}.$$

In fact, it is not hard to modify the Freivalds' algorithm in order to show that, for any $\epsilon \in (0, \frac{1}{2})$, rtP1BCA can recognize $L_{upal(t)}$ with negative one-sided error bound ϵ. Moreover, since the task of any counter can be implemented by two heads, we can argue the following result.

Lemma 3. *Any rtP1BCA can be exactly simulated by a 1P3FA.*

Proof. Let $\mathcal{M}$ and $\mathcal{M}'$ be respectively the given rtP1BCA and the 1P3FA simulating $\mathcal{M}$. The heads of $\mathcal{M}'$ can be named as follows: H_i is the head simulating the input head of $\mathcal{M}$ and H_1 and H_2 are responsible to implement the blind counter of $\mathcal{M}$. The input is sequentially read by H_i as $\mathcal{M}$ does and for any increment (resp., decrement) operation on the counter, H_1 (resp., H_2) moves one square to the right. When H_i reads the right end-marker and enters an accepting state, both H_1 and H_2 are tested whether they are on the same square or not (they start to travel towards to the right end-marker (\$) with the same speed and the test is passed if they read \$ simultaneously). If so, the input is accepted, otherwise, it is rejected. □

Theorem 5. *For any $\epsilon \in (0, \frac{1}{2})$, language $L_{upal(t)}$ can be recognized by a 1P3FA with negative one-sided error bound ϵ, where $t > 0$.*

Corollary 5. *For any $k \geq 3$ and $\epsilon \in (0, \frac{1}{2})$, the class of languages recognized by 1DkFAs is a proper subset of the class of the languages recognized by 1PkFAs with error bound ϵ.*

By using t heads, it is not hard to show that a 1QFA can recognize language $L_{neq(t)}$ with any error bound less than $\frac{1}{3}$, where

$$L_{neq(t)} = \{w \in \{a_1, \ldots, a_t, b_1, \ldots, b_t\}^* \mid \forall i \in \{1, \ldots, t\}(|w|_{a_i} \neq |w|_{b_i})\}.$$

Question 1. *What is the minimum number of heads required by a 1PFA in order to recognize* $L_{neq(t)}$ *with an error bound less than* $\frac{1}{3}$*?*

By using the techniques described in Section 3.1, we can show that $L_{neq(t)}$ is a member of NQAL, where $t > 1$.

Conjecture 2. *For any* $k > 1$*, there exists a* $t > 0$ *such that* $L_{neq(t)}$ *cannot be recognized by any 1N*k*FA.*

Conjecture 3. $L_{gt} = \{w \in \{a, b\}^* \mid |w|_a > |w|_b > 0\}$ *cannot be recognized by a 1QFA with bounded error?*

Question 2. *What is the minimum number of heads required by a 1QFA (or a 1PFA) in order to recognize* $L_{gt(t)}$ *with an error bound less than* $\frac{1}{3}$*, where* $t > 1$ *and* $L_{gt(t)} = \{w \in \{a_1, \ldots, a_t, b_1, \ldots, b_t\}^* \mid \forall i \in \{1, \ldots, t\}(|w|_{a_i} > |w|_{b_i})\}$*?*

3.4. Multihead pushdown automata

It was shown in [9] that $L_{twin(t)}$, namely *twin languages*, cannot be recognized by a 1NPDkA if and only if $t > \binom{k}{2}$, where $t > 0$, $k > 1$, and

$$L_{twin(t)} = \{w_1 c \cdots c w_t c w_t c \cdots c w_1 \mid w_i \in \{a, b\}^*, 1 \leq i \leq t\}.$$

Note that, $L_{twin(t)}$ can be recognized by a 1DkFA whenever $t \leq \binom{k}{2}$ [27] and so for this language neither nondeterminism nor a pushdown storage is helpful.

Theorem 6. $L_{twin(2t)}$ *can be recognized by a 1P*k*FA with negative one-sided error bound* $\frac{1}{2}$*, where* $t = \binom{k}{2}$*,* $t > 0$*,* $k > 1$*.*

Proof. We assume the input of the form – if not, it is rejected exactly –

$$w_1 c \ldots w_{2t} c u_{2t} c \ldots c u_1 \ (w_i, u_i \in \{a, b\}^*, 1 \leq i \leq 2t).$$

At the beginning, the computation is split into two branches, say branch_1 and branch_2, with probability $\frac{1}{2}$. By using k heads, the pairs $(w_1, u_1), \ldots, (w_t, u_t)$ and $(w_{t+1}, u_{t+1}), \ldots, (w_{2t}, u_{2t})$ are compared deterministically in branch_1 and branch_2, respectively. □

Corollary 6. *The class of the languages recognized by 1D2FAs is a proper subset of the class of the languages recognized by 1P2FAs with error bound* $\frac{1}{3}$*.*

Corollary 7. *For any $k \in \mathbb{Z}^+$, the class of languages recognized by 1DPDkAs is a proper subset of the class of the languages recognized by 1QPDkAs (1PPDkAs) with error bound $\frac{1}{3}$.*

It is an open problem whether $L_{twin} (= L_{twin(1)})$ can be recognized by a 1PPDA with bounded error [36]. Therefore, it is interesting to ask the following question.

Question 3. *For a given $t > 0$, let k be the minimum integer such that $L_{twin(t)}$ is recognized by a 1PkFA with an error bound at most $\frac{1}{3}$. Is there any $k' < k$ such that $L_{twin(t)}$ can be recognized by a 1PPDk′A with error bound $\frac{1}{3}$?*

It was shown in [36] that L_{twin} can be recognized by a rtQPDA with negative one-sided bounded error $\frac{1}{2}$. Therefore, a quantum machine can make one more comparison of a pair by using a pushdown storage for any twin language.

Corollary 8. *For a given $t > 0$, let k be the minimum number such that $L_{twin(t)}$ is recognized by a 1PkFA with negative one-sided error bound $\frac{1}{2}$. Then, $L_{twin(t)}$ can be recognized by a 1QPD(k-1)A with negative one-sided error bound $\frac{1}{2}$.*

Question 4. *Is the class of languages recognized by 1PPDkAs with error bound $\frac{1}{3}$ is properly contained in the class of languages recognized by 1QPDkAs with error bound $\frac{1}{3}$?*

If we allow the error bound bigger than $\frac{1}{3}$, we can obtain the following results.

Theorem 7. *$L_{twin(t)}$ can be recognized by a rtQPDA with negative one-sided error bound $1 - \frac{1}{2t}$, where $t > 0$.*

Proof. We assume the input of the form – if now, it is rejected exactly –

$$w_1 c \cdots c w_t c u_t c \cdots c u_1 \ (w_i, u_i \in \{a, b\}^*, 1 \leq i \leq t).$$

An integer, say i, is selected from the set $\{1, \ldots, t\}$ with probability $\frac{1}{t}$ at the beginning. Then, the substrings w_i and u_i are compared by the rtQPDA algorithm for L_{twin} given in [36]. □

Theorem 8. *$L_{twin(t)}$ can be recognized by a 1P2FA (or 1Q2FA) with negative one-sided error bound $1 - \frac{1}{t}$, where $t > 0$.*

Acknowledgment. We thank Juraj Hromkovič for his helpful answers to our questions regarding blind counters.

A. Proof of Theorem 1

Theorem 1. L_{ijk} is in NQAL.

Proof. By tensoring two GFAs (see Page 147 in [26]) $\mathcal{G}_1 = (Q_1, \Sigma, \{A_{\sigma\in\Sigma}\}, v_0, f)$ and $\mathcal{G}_2 = (Q_2, \Sigma, \{B_{\sigma\in\Sigma}\}, u_0, g)$, we obtain a new GFA $\mathcal{G}'$ ($\mathcal{G}_1 \otimes \mathcal{G}_2$), specified as

$$\mathcal{G}' = (Q_1 \times Q_2, \Sigma, \{A_\sigma \otimes B_\sigma \mid \sigma \in \Sigma\}, v_0 \otimes u_0, f \otimes g),$$

such that for any $w \in \Sigma$,

$$f_{\mathcal{G}'}(w) = f_{\mathcal{G}_1}(w) f_{\mathcal{G}_2}(w).$$

Let $\Sigma = \{a, b, c\}$ be the input alphabet. We design a GFA $\mathcal{G}_{a-b}$ to calculate the value of $(|w|_a - |w|_b)$ as its accepting value for any $w \in \Sigma^*$, i.e.

$$\mathcal{G}_{a-b} = (Q, \Sigma, \{A_{\sigma\in\Sigma}\}, v_0, f),$$

where $Q = \{q_1, q_2\}$, $v_0 = (0 \;\; 1)^T$, $f = (1 \;\; 0)$, and

$$A_a = \begin{pmatrix} 1 & 1 \\ 0 & 1 \end{pmatrix}, \quad A_b = \begin{pmatrix} 1 & -1 \\ 0 & 1 \end{pmatrix}, \quad A_c = \begin{pmatrix} 1 & 0 \\ 0 & 1 \end{pmatrix}.$$

At the beginning, the values of q_1 and q_2 are 0 and 1, respectively. Whenever an a (resp., a b) is read, the value of q_1 (resp., q_2) is increased (resp., decreased) by 1. At the end, the value of q_1 is assigned as the accepting value. That is, $f_{\mathcal{G}_{a-b}}(w) = |w|_a - |w|_b$.

Similarly, we can design two GFAs $\mathcal{G}_{a-c}$ and $\mathcal{G}_{b-c}$ to calculate the values of $(|w|_a - |w|_c)$ and $(|w|_b - |w|_c)$ as their accepting values, respectively, for any $w \in \Sigma^*$.

Moreover, we can design a GFA $\mathcal{G}_{a^+b^+c^+}$ to assign 1 as the accepting value for the strings of the form $a^+b^+c^+$ and 0, otherwise:

$$\mathcal{G}_{a^+b^+c^+} = (Q, \Sigma, \{A_{\sigma\in\Sigma}\}, v_0, f)$$

where $Q = \{q_1, q_2, q_3, q_4\}$, $v_0 = (1 \;\; 0 \;\; 0 \;\; 0)^T$, $f = (0 \;\; 0 \;\; 0 \;\; 1)$, and

$$A_a = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 1 & 1 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad A_b = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 1 & 1 & 0 \\ 0 & 0 & 0 & 0 \end{pmatrix}, \quad A_c = \begin{pmatrix} 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & 1 \end{pmatrix}.$$

Now, we can obtain a GFA $\mathcal{G}_{ijk}$ for L_{ijk} as

$$\mathcal{G}_{ijk} = \mathcal{G}_{a^+b^+c^+} \otimes (\mathcal{G}_{a-b} \otimes \mathcal{G}_{a-b}) \otimes (\mathcal{G}_{a-c} \otimes \mathcal{G}_{a-c}) \otimes (\mathcal{G}_{b-c} \otimes \mathcal{G}_{b-c}),$$

which calculates the value of

$$(|w|_a - |w|_b)^2 (|w|_a - |w|_c)^2 (|w|_b - |w|_c)^2$$

for the strings of the form $a^+b^+c^+$ and returns 0, otherwise. In other words, $f_{\mathcal{G}_{ijk}}(w)$ is a positive integer if w is a member of L_{ijk} and it is zero if w is not a member of L_{ijk}. $\square$

B. Proof of Theorem 2

Theorem 2. If L is recognized by a rtDkBCA, then $\overline{L}$ $\in$NQAL, where $k > 0$.

Proof. Without the loose of generality, we can assume that the counter operation(s) of a rtDkBCA, say $\mathcal{D}$, can be determined by the internal state to be entered after each transition. Thus, the transitions of $\mathcal{D}$ can be defined from $Q \times \tilde{\Sigma}$ to Q, where $Q = \{q_1, \ldots, q_n\}$ is the set of the internal state and $n > 0$, where q_1 is the initial state. Equivalently, for each $\sigma \in \tilde{\Sigma}$, we can define a matrix (transition matrix), say T_σ, whose columns and rows are indexed by the internal states such that the $(j,i)^{th}$ entry of T_σ represents the transition value from state q_i to q_j. Due to its deterministic nature, these transition matrices are (left) stochastic having zero-one stochastic columns.

The state-transition of $\mathcal{D}$ can be linearized. For this purpose, we define the following components:

- Q_a is the set of accepting states,
- $v_0 = (1 \;\; 0 \;\; \cdots \;\; 0)^T$ is an n-dimensional column vector, and
- f is an n-dimensional row vector such that $f[i] = 1$ if $q_i \in Q_a$ and $f[i] = 0$ if $q_i \notin Q_a$, where $1 \leq i \leq n$.

That is, for a given input string $w \in \Sigma^*$, the state-transition of $\mathcal{D}$ is traced by a (stochastic) column vector, i.e.

$$v_i = T_{\tilde{w}_i} v_{i-1}$$

and

$$v_{|\tilde{w}|} = T_{\$} T_{w_{|w|}} \cdots T_{w_1} T_{\cent} v_0,$$

where $1 \leq i \leq |\tilde{w}|$. It can be easily verified that if $\mathcal{D}$ enters to q_j at the end of the computation if and only if $v_{\tilde{w}}[j] = 1$, where $1 \leq j \leq n$. (Note that, each intermediate v_i is also a stochastic zero-one vector, where $1 \leq i \leq |\tilde{w}|$.)

Let p_l be the l^{th} prime $(1 \leq l \leq k)$. In the above schema, the counter operations of $\mathcal{D}$ can be simulated by using a simple number-theoretic method: when the l^{th} counter of $\mathcal{D}$ is updated by 1 (resp., 0 or -1), the nonzero entry of v_i is updated by multiplying with p_l (resp., 1 or $\frac{1}{p_l}$), where $1 \leq l \leq k$ and $1 \leq i \leq |\tilde{w}|$. This method can be embedded into the transition matrices. That is, if the value(s) of counter(s) is (are) updated with respect to $c \in \{-1, 0, 1\}^k$ when entering state $q_j \in Q$, in each $T_{\sigma \in \tilde{\Sigma}}$, the nonzero entries on the j^{th} row is replaced with

$$\prod_{l=1}^{k} (p_l)^{c[l]}.$$

We denote updated matrices as $T'_{\sigma\in\tilde{\Sigma}}$.

> Suppose that the value(s) of the counter(s) is (are) $C \in \mathbb{Z}^k$ at the end of the computation and the computation ends in $q_j \in Q$ on input $w \in \Sigma^*$. Then, it can be verified in a straightforward way that
>
> $$v_{|\tilde{w}|}[j] = \prod_{l=1}^{k} (p_l)^{C[l]}, \tag{3}$$
>
> which is 1 if and only if each counter value is zero.

Let $T''_{\sigma\in\tilde{\Sigma}}$ be $(n+1)\times(n+1)$-dimensional matrices obtained form T'_σ as

$$T''_\sigma = \left(\begin{array}{c|c} & 0 \\ T'_\sigma & \vdots \\ & 0 \\ \hline 0\cdots0 & 1 \end{array} \right).$$

We design a GFA $\mathcal{G}$ based on $\mathcal{D}$ as follows:

$$\mathcal{G} = (Q', \Sigma, \{A_{\sigma\in\Sigma}\}, v'_0, f'),$$

where $Q' = Q \cup \{q_{n+1}\}$,

$$v'_0 = T''_{¢} \begin{pmatrix} 1 \\ 0 \\ \vdots \\ 0 \\ -1 \end{pmatrix}, \quad f' = (f \mid 1)T''_{\$}, \text{ and } A_\sigma = T''_\sigma.$$

Hence, by using the scenario given in (3), we can verify that

- if $q_j \in Q_a$, then $f_{\mathcal{G}}(w) = \left(\prod_{l=1}^{k}(p_l)^{C[l]}\right) - 1$, i.e.
  - $f_{\mathcal{G}}(w) = 0$ if each counter value is zero and
  - $f_{\mathcal{G}}(w) \neq 0$ if at least one counter value is not zero;
- if $q_j \notin Q_a$, then $f_{\mathcal{G}}(w) = -1$.

Let L be the language recognized by $\mathcal{D}$ and $\mathcal{G}^2 = \mathcal{G}\otimes\mathcal{G}$. Then, for $w \in L$ (resp., $w \notin L$), $f_{\mathcal{G}^2}(w) = 0$ (resp., $f_{\mathcal{G}^2}(w) > 0$). Thus, $\overline{L} \in$ NQAL. □
